Abstract

Introduction: Antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis (AAV) is characterised by the autoinflammation and necrosis of blood vessel walls. The renal involvement is commonly characterised by a pauci-immune crescentic glomerulonephritis (PICGN) with a very rapid decline in renal function. Cathelicidin LL37, an endogenous antimicrobial peptide, has recently been implicated in the pathogenesis of autoimmune diseases. To assess whether serum LL37 reflects renal crescentic formation, we measured the serum levels of LL37 in AAV patients with and without crescentic glomerulonephritis (crescentic GN) as compared to healthy controls (HCs). We also analysed the correlation of the serum levels of LL37 and interferon- α (IFN- α) with the clinical characteristics of the patients.

Methods: The study population consisted of 85 AAV patients and 51 HCs. In 40 ANCA-positive patients, a parallel analysis was performed, including the assessment of LL37 and IFN- α levels in the serum and renal biopsies. Of those studied, 15 AAV patients had biopsy-proven crescentic GN, and 25 AAV patients lacked crescent formation. The serum levels of cathelicidin LL37 and IFN- α were both measured by ELISA, and the clinical and serological parameters were assessed according to routine procedures. Immunofluorescence staining was performed on frozen sections of kidney needle biopsies from AAV patients with crescentic GN.

Results: The serum levels of LL37 and IFN- α were significantly increased in AAV patients with crescentic GN compared to AAV patients without crescentic formation and HCs, and patients with high LL37 and IFN- α levels were more likely to be in the crescentic GN group. The LL37 levels were positively correlated with the IFN- α levels, and both LL37 and IFN- α levels showed a positive correlation with serum creatinine and no correlation with complement C3. The renal tissue of crescentic GN patients showed expression of LL37 and IFN- α at the Bowman's capsule and extracellular sites, suggesting the active release of LL37 and IFN- α .

Conclusions: Significantly higher levels of LL-37 and IFN- α were observed in AAV patients, particularly those with crescentic formation, and LL37 and IFN- α were expressed in the renal tissue of patients with crescentic GN. These data suggest that serum levels of LL37 and IFN- α may reflect both local renal inflammation and systemic inflammation.

Introduction

Anti-neutrophil cytoplasm antibody (ANCA)-associated vasculitis (AAV) represents a group of systemic autoimmune diseases including Wegener's granulomatosis, microscopic polyangiitis, Churg–Strauss syndrome and renal limited vasculitis [1]. Renal involvement is frequently manifested as focal segmental necrotising glomerulonephritis (GN), typically pauci-immune crescentic glomerulonephritis (PiCGN). Myeloperoxidase (MPO) and proteinase-3 (PR3) have been identified as targets of classical ANCA and have proved invaluable for the diagnosis and monitoring of disease activity [1]. In addition, the presence of autoantibodies to lysosomal membrane protein-2 (LAMP-2) represents an additional ANCA subtype [2-4]. However, the mechanisms underlying the pathogenesis of PiCGN remain elusive. As an endogenous antimicrobial peptide, LL37 has recently been implicated in the pathogenesis of autoimmune diseases [5]. Autoinflammatory conditions such as psoriasis and systemic lupus erythematosus can be driven by plasmacytoid dendritic cells (pDCs), which produce large amounts of interferon alpha (IFN α) in the presence of DNA and cathelicidin LL37 [6,7]. Recently, DNA-containing LL37 was shown to be involved in the renal damage in AAV, with increased concentrations of IFN α in serum samples from individuals with active AAV [8].

Cathelicidin LL37 is a member of an antimicrobial peptide family found within the lysosomes of macrophages, and polymorphonuclear leukocytes serve a critical role in immune defence against invasive bacteria [9]. For example, neutrophil extracellular traps (NETs) are a unique method by which neutrophils can cause cell death via the release of a meshwork of chromatin fibres decorated with granule-derived antimicrobial peptides; however, these NETs are a potential source of auto-antigens and may contribute to organ damage and vascular disease [10]. These NET-derived constituents stimulate pDCs to release IFN α , which establishes a positive feedback loop in which NETs stimulate IFN α release from pDCs, and this cytokine then primes neutrophils for additional NET formation [6,10,11].

In this study, we hypothesised that the serum levels of LL37 would reflect systemic and renal local inflammation in patients with PiCGN. Therefore, we investigated LL37 and IFN α levels using enzyme-linked immunosorbent assays (ELISAs) in AAV patients and correlated these results to the serological parameters assessed.

Methods

Patients

Adult subjects with AAV, who were diagnosed according to the Chapel Hill definition [12], were recruited from the Department of Nephrology, Xinqiao Hospital, Third Military Medical University. The patient characteristics are presented in Table 1. Serum samples were collected from the patients and healthy controls (HCs). Among the 85 patients, 40

patients underwent renal biopsies concomitantly obtained with the serum samples, and all biopsies were reviewed and classified by an experienced nephropathologist according to the revised criteria for PiCGN. Criteria used in the study to define PiCGN by immunofluorescence analysis for frozen tissue sections presented deficiency of immunoglobulin and complements. PR3-ANCA and MPO-ANCA were evaluated using EUROBlot kits (DL-1200-6421-3G; Euroimmun; Lübeck, Germany) and indirect immunofluorescence (FA-1200-2010; Euroimmun; Lübeck, Germany) according to the protocol provided by the manufacturer. The levels of creatinine, blood urea nitrogen and complement factor C3 in the sera were determined using routine techniques. Crescentic GN was defined as crescents in >50% glomeruli. Frozen sections of renal biopsy specimens obtained from 40 patients, among of them, 15 patients with crescentic GN and 25 patients without crescentic GN were included in the present study. The study protocols were approved by the ethics committee board of Xinqiao Hospital, and all subjects gave written informed consent.

Reagents

Fluorescein isothiocyanate (FITC) anti-human CD16 was purchased from Biolegend (San Diego, CA, USA). Anti-human LAMP-2 mouse monoclonal antibody (H4B4), anti-human LAMP-2 mouse monoclonal antibody-FITC, anti-human PR3 mouse monoclonal antibody-FITC (WGM2), anti-human MPO mouse monoclonal antibody-FITC (266.6 K2), anti-LL37 (pAbC14), anti-IFN α (pAbFL-189) and normal mouse IgG1 were purchased from Santa Cruz (Heidelberg, Germany). Anti-human histone H3 rabbit polyclonal antibody was purchased from Abcam (Cambridge, UK). All secondary antibodies conjugated with fluorescence were purchased from ZSbio (Beijing, China). Phorbol 12-myristate 13-acetate was purchased from Sigma-Aldrich (St Louis, MO, USA). HBSS (without Ca²⁺ and Mg²⁺), RPMI-1640 medium (phenol red-free) and penicillin/streptomycin solution were purchased from Invitrogen (San Diego, CA, USA). The 12-mm round glass cover slips were purchased from Thermo Fisher Scientific (Waltham, MA, USA). Polymorphprep™ was purchased from Axis-Shield (Oslo, Norway). The red blood cell lysis buffer was purchased from Roche Diagnostics (Mannheim, Germany). The immunostaining fix solution, immunostaining blocking buffer, immunostaining primary antibody dilution buffer, immunofluorescence staining secondary antibody dilution buffer and anti-fade mounting medium were purchased from Beyotime (Shanghai, China). Anti-human BDCA2 mouse monoclonal antibody-FITC (130-090-510) and anti-human BDCA2 mouse monoclonal antibody-PE (130-090-511) were purchased from Miltenyi Biotec (Bergisch Gladbach, Germany). The ELISA kits for LL37 (HK321) and IFN α (3423-1A-20) were purchased from Hycult Biotech (Uden, Netherlands) and MabTech (Nacka Strand, Sweden), respectively.

Table 1 Clinical characteristics of patients with sera included in the cohort

	Crescentic-positive AAV	Crescentic-negative AAV	Without renal biopsy
Total	15	25	45
Male/female	7/8	9/16	19/26
Age (years)	61 (8 to 78)	44 (7 to 76)	55 (20 to 78)
MPO-positive	14	22	40
Protease 3-positive	2	4	5
Complement 3 (g/l)	0.68 (0.44 to 1.18)	0.95 (0.06 to 1.83)	0.80 (0.36 to 1.99)
Serum creatinine ($\mu\text{mol/l}$)	736.5 (147.6 to 1,316) ^{##, *}	165.0 (35.2 to 812.4)	381.1 (39.3 to 881)
24-hour proteinuria (g/24 hours)	0.47 (0.17 to 3.58)	0.83 (0.3 to 6.4)	1.80 (0.01 to 7.8)

Data presented as number or median (range). AAV, anti-neutrophil cytoplasmic antibody-associated vasculitis; MPO, myeloperoxidase. ^{##}Difference between the crescentic-positive AAV patients and crescentic-negative AAV patients ($P < 0.01$). ^{*}Difference between the crescentic-positive AAV patients and AAV patients without a renal biopsy ($P < 0.05$).

Note: Each group had one patient shown double positive MPO- and PR3- ANCA in crescentic-positive AAV and crescentic-negative AAV, respectively.

Isolation of neutrophils

Human neutrophils were isolated from HCs or patients with PiCGN by density centrifugation using Polymorphprep™ and red blood cell lysis buffer [13]. Briefly, 5 ml blood containing ethylenediamine tetraacetic acid was layered onto 5 ml Polymorphprep™. After 35 minutes of centrifugation at 500 g, the neutrophils were separated from the polymorphonuclear leukocyte-rich pellet. Residual erythrocytes were eliminated by red blood cell lysis. The neutrophil purity was routinely ~95%, as assessed by forward-scatter and side-scatter flow cytometric analyses [8]. Unless otherwise stated, the cells were resuspended in RPMI medium (phenol red-free) supplemented with 1% penicillin/streptomycin. Then, 5×10^6 neutrophils/ml were seeded onto tissue culture plates for culture and 5×10^5 neutrophils/ml were seeded onto glass coverslips for immunofluorescence staining. The cells were incubated at 37°C in the presence of 5% CO₂.

Enzyme-linked immunosorbent assay

The levels of LL37 and IFN α from sera or cell culture supernatants were quantified by ELISA according to the protocols provided by the manufacturers. The sensitivity was 0.1 ng/ml for LL37 and 7.8 pg/ml for IFN α .

Scanning electron microscopy

Freshly purified neutrophils were allowed to adhere to glass coverslips in RPMI-1640 medium. After incubation for 30 minutes at 37°C in 5% CO₂, the cells were stimulated with 20 $\mu\text{g/ml}$ LAMP-2 antibody or left untreated. The neutrophils were then fixed in 2.5% glutaraldehyde for 2 hours at 4°C. After washing with physiological saline three times, the samples were dehydrated through a graded ethanol series. The cover slips were then transferred into a critical point dryer and dried. The surface of the specimen was coated with a 5 nm platinum/carbon layer using a thin layer evaporator. The samples were then viewed with a scanning electron microscope.

Immunofluorescence staining and detection by confocal microscopy

Immunofluorescence staining was performed on frozen sections of kidney needle biopsies from patients with PiCGN as described previously [8]. Briefly, after fixation in paraformaldehyde, the specimens were incubated with anti-LL37 (pAbC14), anti-histone H3 (pAbab8284), anti-IFN α (pAbFL-189) and anti-BDCA-2 (mAbCD303) antibodies or isotype control, followed by the appropriate secondary antibodies. DNA was stained with 4',6-diamidino-2-phenylindole. The neutrophils were seeded onto lysinated glass slides in a 24-well cell culture plate and incubated for 1 hour in a CO₂ incubator at 37°C. The cells were left unstimulated or were stimulated with either 100 nM phorbol 12-myristate 13-acetate or 20 $\mu\text{g/ml}$ LAMP-2 antibody for up to 180 minutes at 37°C in 5% CO₂. Subsequently, the cells were fixed and permeabilised. After rehydration with phosphate-buffered saline at room temperature, the cells were incubated with blocking buffer overnight at 4°C, and then the specimens were incubated with fluorescently labelled antibodies. The chromatin was stained with an anti-histone H3 rabbit antibody. The images were acquired as projections of a confocal stack.

Statistical analyses

The experiments were performed in triplicate at least three separate times. Data are presented as the mean \pm standard error of the mean and were analysed using GraphPad Prism software 5 (GraphPad Software, San Diego, CA, USA). Where appropriate, either two-tailed Student's *t* tests or the Kruskal–Wallis and Mann–Whitney *U* tests were used. Differences were considered significant at $P < 0.05$.

Results

Serum LL37 levels are increased in AAV patients

To analyse the correlation between the serum levels of LL37 and AAV, we first performed ELISAs to determine the LL37 levels in 136 serum samples collected from 85

unrelated patients with documented AAV (50 females, 35 males; female/male ratio 10:7) (Table 1) and 51 HCs. The AAV sera contained higher levels of LL37, with a mean concentration of 100.3 ng/ml, as compared with the HC sera, which showed a mean concentration of 28.53 ng/ml ($U = 829.00$, $P < 0.01$; Figure 1A). Serum levels of LL37 >100.3 ng/ml were arbitrarily considered to represent high levels, and those <100.3 ng/ml were considered to represent low levels. Among the 40 patients with renal biopsy, as shown in Figure 1B, the renal tissue of patients with crescentic GN showed higher levels of LL37 as compared with those from patients with noncrescentic GN ($P < 0.01$) and HCs ($P < 0.001$). The serum levels of LL37 in patients without crescentic GN were also significantly higher than those in HCs ($P < 0.01$). Forty patients underwent renal biopsy and 22 of them expressed high serum levels of LL37 (>100.3 ng/ml), and 13 of these high-expression patients had crescentic GN. In contrast, only two of the 18 patients expressing low serum levels of LL37 (<100.3 ng/ml) had crescentic GN ($\chi^2 = 9.724$, $P = 0.002$; Figure 1C). These results indicated that patients with high LL37 expression had a greater risk of having crescentic GN as compared with patients with low LL37 expression.

Serum IFN α levels are increased in AAV patients

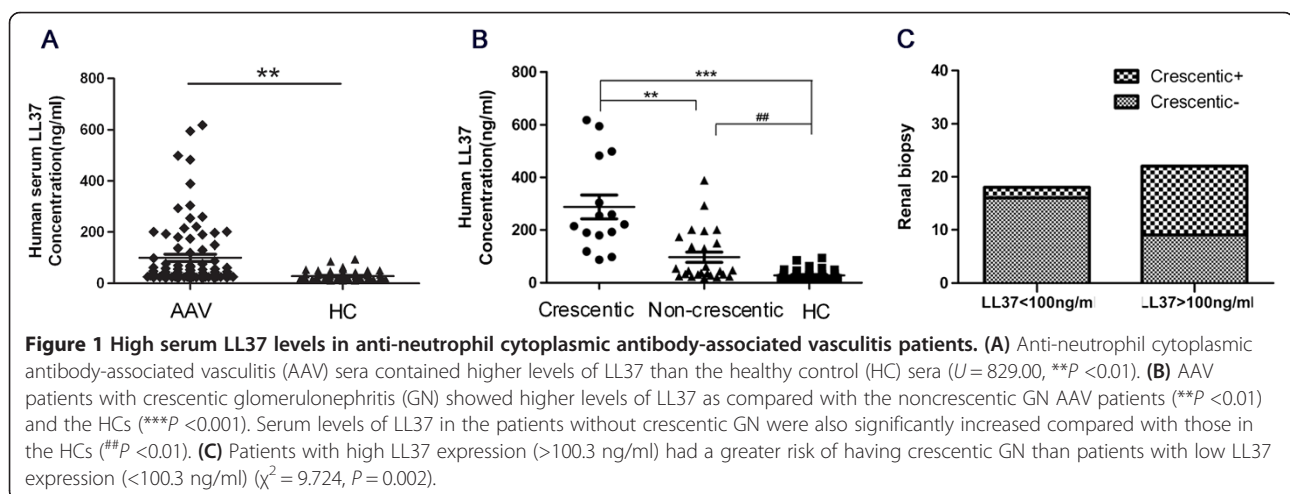

We also performed ELISAs to analyse the serum IFN α levels in 136 serum samples collected from the aforementioned 85 patients. We found that the AAV sera contained higher levels of IFN α , with a mean concentration of 958.5 pg/ml, compared with the HC sera, which showed a mean concentration of 252.1 pg/ml ($U = 1438.00$, $P = 0.000$; Figure 2A).

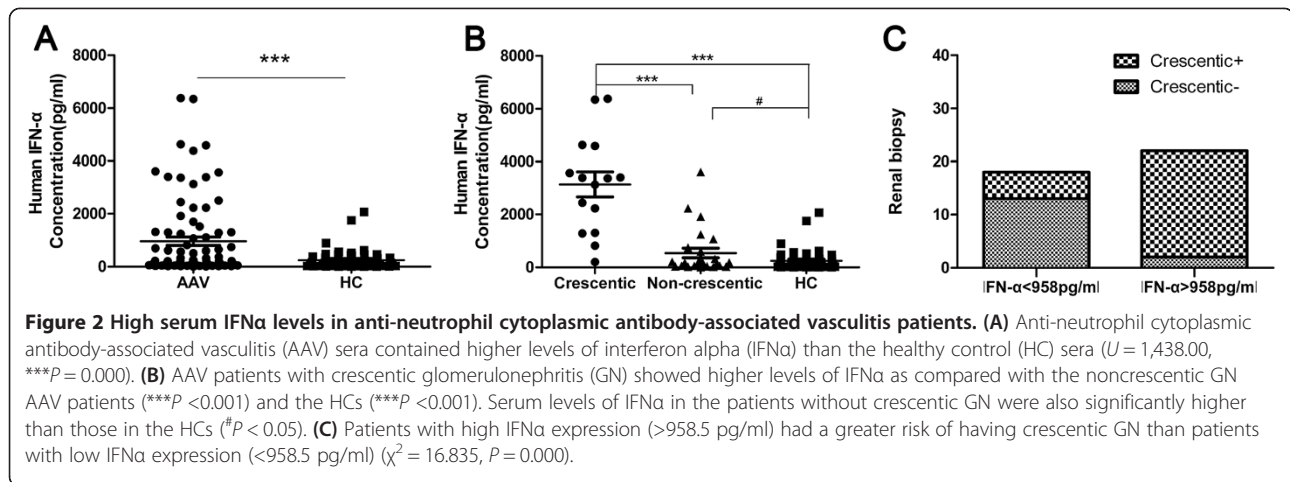

Serum levels of IFN α >958.5 pg/ml were arbitrarily considered to represent high levels, whereas those <958.5 pg/ml were considered to represent low levels. Among the 40 patients with renal biopsy, as shown in

Figure 2B, 15 crescentic GN patients showed high-level IFN α expression as compared with 25 of the noncrescentic GN patients ($P < 0.001$) and the HCs ($P < 0.001$). The IFN α serum level of the patients without crescentic GN were also significantly higher than those in HCs ($P < 0.05$). Of the 40 patients who provided a renal biopsy, 22 showed high levels of IFN α (>958.5 pg/ml), and 13 of these 22 patients had crescentic GN. In contrast, only two of the 18 patients expressing low serum levels of IFN α (<958.5 pg/ml) had crescentic GN ($\chi^2 = 16.835$, $P = 0.000$; Figure 2C). These results indicated that patients expressing high IFN α levels had a greater risk of crescentic formation in the glomerulus in comparison with patients expressing low levels of IFN α .

Correlation of the serum LL37 and IFN α levels with the serological parameters

Given that the LL37 and IFN α serum levels were increased in AAV patients, particularly in those with crescentic GN, we further investigated whether the serum levels of LL37 were correlated with the IFN α levels and whether the levels of LL37 and IFN α were correlated with the serum levels of creatinine and complement C3. We found a positive correlation between the serum LL37 and IFN α levels ($R = 0.577$, $P = 0.000$; Figure 3A) as well as significant positive correlations between the serum levels of LL37 and creatinine ($R = 0.437$, $P = 0.000$; Figure 3B) and between the serum levels of IFN α and creatinine ($R = 0.337$, $P = 0.004$; Figure 3C). However, neither LL37 nor IFN α showed any correlation with complement C3 (LL37: $R = 0.020$, $P = 0.871$; IFN α : $R = -0.12$, $P = 0.922$) (Figure 3D,E). To further investigate whether LL37 and IFN α reflect systemic inflammation, we analysed the sera levels of LL-37 and IFN α before and after treatment ($n = 7$). We found that both LL-37 and IFN α levels had degraded after immunosuppressive therapy (Additional file 1).

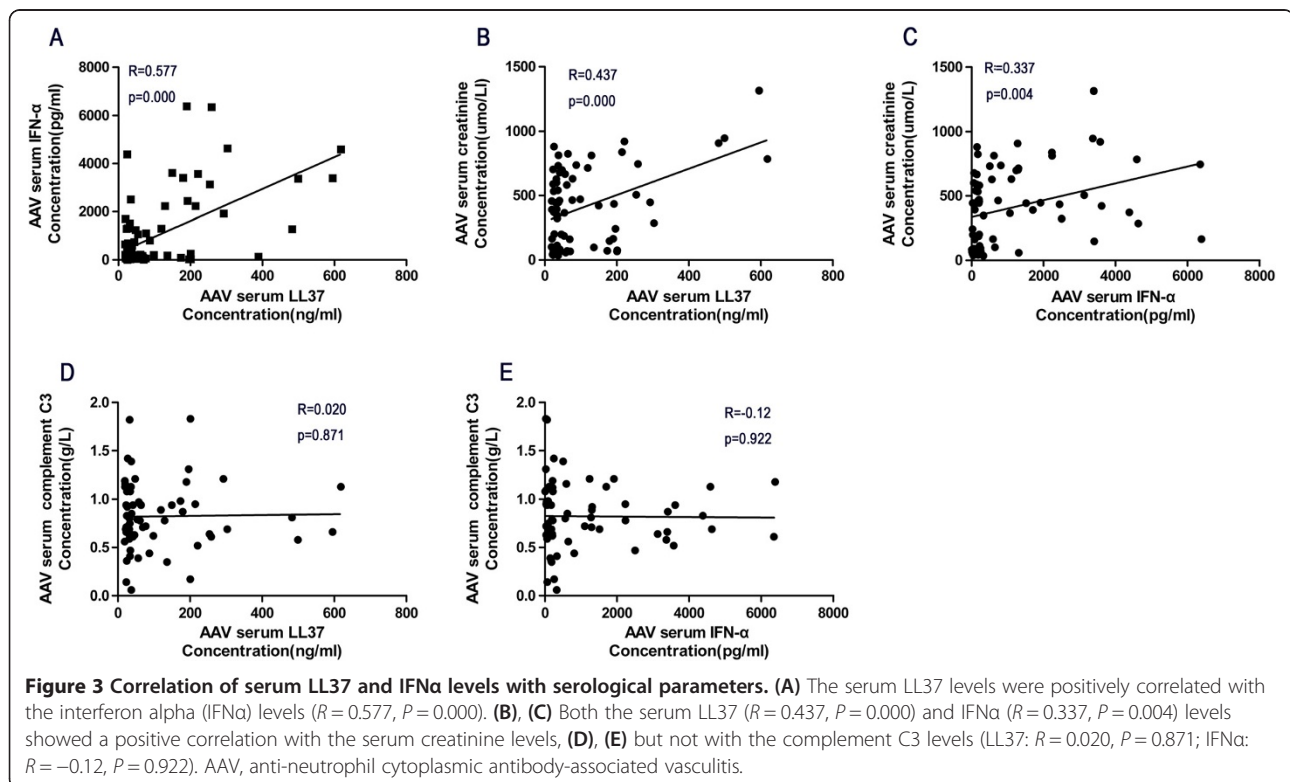

Release of LL37 and IFN α in the kidney

To assess the roles of LL37 and IFN α in renal inflammation, we evaluated the presence and localisation of LL37 and IFN α in renal biopsies from AAV patients with crescentic GN. We found that the kidney tissues from AAV patients showed strong expression of LL37, especially in Bowman's capsule. We also found that LL37 expression co-localised with neutrophil and pDC (stained for BDCA2) infiltrates in the affected glomeruli and the interstitium (Figure 4A,B), suggesting that LL37 expression occurs predominantly during crescentic GN.

As autoinflammatory conditions such as psoriasis can be driven by pDCs, which produce large amounts of IFN α , we next examined the expression of IFN α in the kidney tissues. Immunostaining revealed the co-localisation of IFN α and LL37 in the kidney tissues from AAV patients (Figure 4C). However, there were only mild immunofluorescence signals stained with IFN α and LL37 in the renal tissues from patients without crescents (Figure 4D), suggesting that LL37 may mediate pDC activation to produce IFN α in renal local inflammatory in AAV.

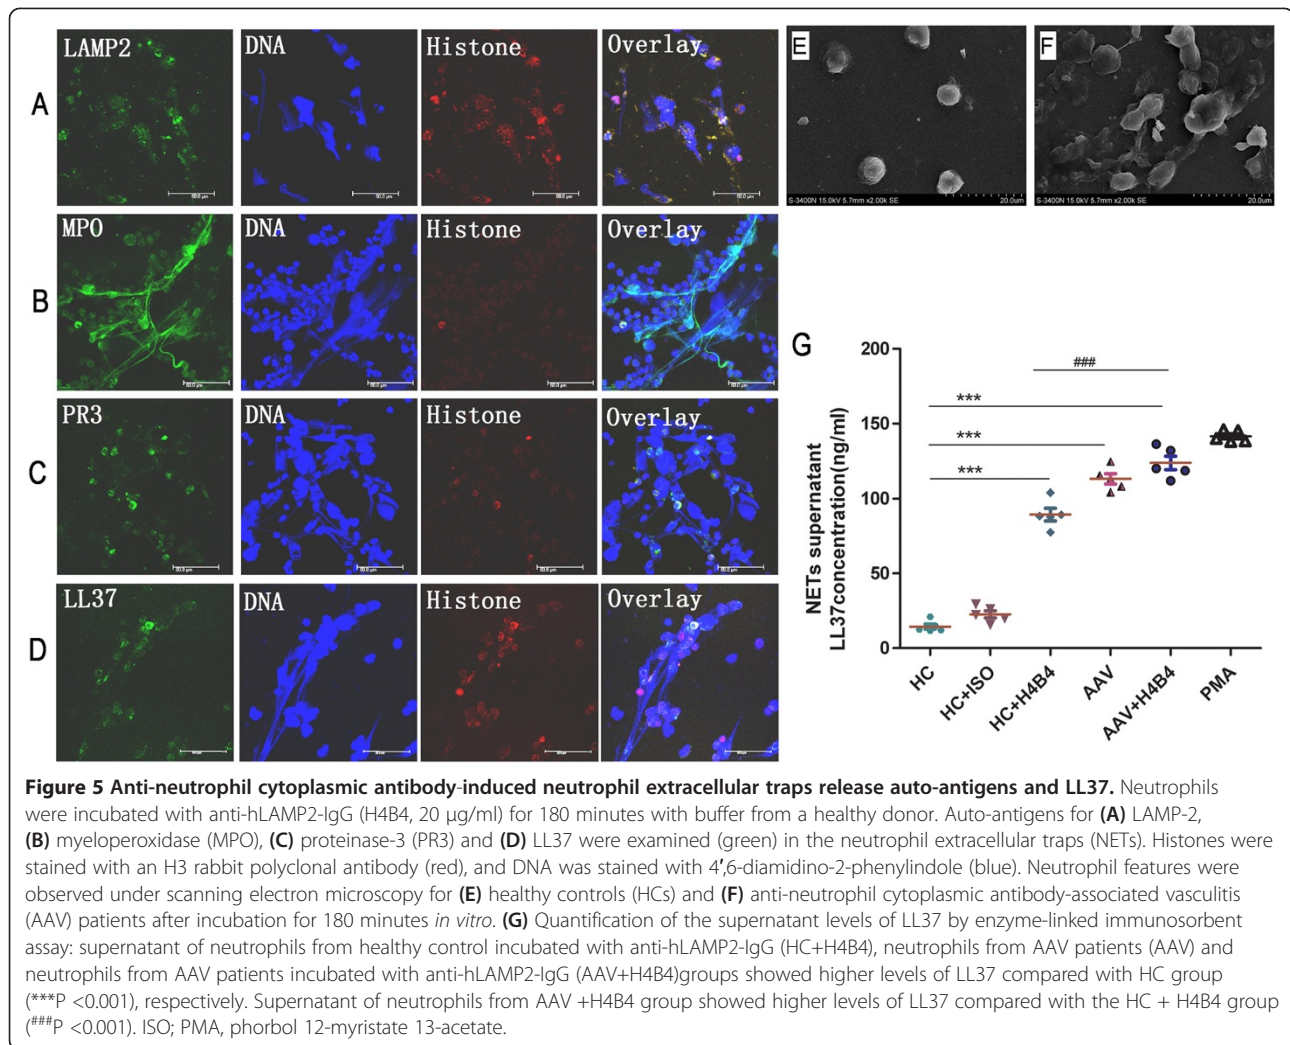

Figure 4 Expression of LL37, IFN α and BDCA2 in anti-neutrophil cytoplasmic antibody-associated vasculitis patients with crescentic glomerulonephritis. (A), (B) Representative images showing the co-localisation of LL37 (red) and BDCA2, a marker of plasmacytoid dendritic cells (green), in the glomeruli of frozen renal biopsy sections after immunofluorescence staining. (C) Co-localisation of interferon alpha (IFN α ; red) and LL37 (green) in renal biopsy sections from anti-neutrophil cytoplasmic antibody-associated vasculitis (AAV) patients with crescentic glomerulonephritis (GN). (D) Co-localisation of IFN α (red) and LL37 (green) in renal biopsy sections from AAV patients without crescentic GN.

Release of auto-antigens and cathelicidin LL37 from neutrophil extracellular traps

ANCA plays a critical role in the vascular damage associated with AAV [14]. Kessenbrock and colleagues reported strong NET formation in patients with AAV [8], and the presence of anti-LAMP-2 antibodies has been suggested to represent a new subtype of ANCA, with a high prevalence in PiCGN [2,4,15]. Therefore, we asked whether targeted auto-antigens and antimicrobial peptides would be present in NETs stimulated by anti-LAMP-2-IgG. As expected, the immunofluorescent analysis of NETs revealed that LAMP-2 co-localised with extracellular chromatin fibres (Figure 5A). We also observed that PR3 and MPO were expressed within the NETs (Figure 5B,C), as reported previously [8], and we found that LL37 expression was enriched in parts of the extracellular chromatin fibres (Figure 5D). After culturing

for 180 minutes, neutrophils isolated from PiCGN patients and HCs showed the typical features of NETosis, including web-like structures, as visualised by scanning electron microscopy (Figure 5E,F). To investigate the release of LL37 in the NET supernatant, neutrophils isolated from AAV patients or HCs were treated with anti-LAMP-2-IgG (AAV + H4B4, $n = 5$; HC + H4B4, $n = 5$), an isotype control (HC + ISO, $n = 5$) or phorbol 12-myristate 13-acetate as a positive control ($n = 5$) [8]. After 180 minutes, the supernatant was collected and measured by ELISA, and the results indicated that the HC + H4B4 group supernatant showed higher levels of LL37 as compared with the HC or HC + ISO groups ($P < 0.001$). Moreover, the AAV + H4B4 supernatant showed higher levels of LL37 compared with the HC + H4B4 supernatant ($P < 0.001$) (Figure 5G). No IFN α was detected in the supernatant by ELISA. We observed MPO, a marker of neutrophils, showing co-

localisation with LL37, IFN α and BDCA-2 in AAV patients with crescentic GN (Additional file 2). To further clarify the source IFN α , pDCs were isolated by magnetically activated cell sorting using the BDCA-4 dendritic cell isolation kit (Miltenyi Biotec). pDCs (5×10^4 /ml) were incubated with supernatants from neutrophils treated as above mentioned, with 3 μ g/ml ODN 2216 pDCs as positive control for 24 hours. Supernatants were harvested to detect the level of IFN α and LL-37 by ELISA. We found that IFN α was released by pDC incubation with supernatants of anti-LAMP-2 antibody-treated neutrophils and ODN2216 for 24 hours (Additional file 3). No LL-37 was released from pDC.

Discussion

The present study is the first to demonstrate that LL37 levels are significantly increased in AAV patients, especially in those with PiCGN. The serum levels of LL37 and IFN α were positively correlated with crescentic formation and also positively correlated with the serum levels of creatinine. Furthermore, we found evidence that LL37

and IFN α expression were co-localised in inflammatory kidney tissue. There were also higher levels of LL37 released in AAV patients as compared with HCs, as determined by NET formation *in vitro*.

PiCGN is a serious manifestation in patients with AAV and can rapidly progress to end-stage renal failure. Despite the large number of studies, the pathogenesis of PiCGN has not been fully clarified. Recently, the constituents derived from NETs, such as high-mobility group box-1 protein, have been shown to play an important role in the renal pathology of systemic lupus erythematosus patients, potentially reflecting both local renal inflammation and systemic inflammation [16,17]. The role of cathelicidin LL37 released from these NETs has been demonstrated in autoimmune and chronic inflammatory diseases, especially those with renal manifestations such as systemic lupus erythematosus and psoriasis [6,7]. However, no studies have been performed to evaluate the serum levels of LL37 to determine whether LL37 expression is a reflection of systemic and/or renal local inflammation in AAV patients. We found

that the serum levels of LL37 were significantly increased in AAV patients, especially in those with PiCGN compared with patients without crescentic formation and HCs. In line with a previous study, the serum levels of IFN α were significantly increased in patients with active AAV [8], and we also found that the serum levels of IFN α were increased similarly in AAV patients with PiCGN. However, the origin of LL37 – that is, whether it is produced outside the kidney or locally within the inflamed kidney – remains unresolved.

The precise events leading to glomerular inflammation and damage in ANCA-related PiCGN remain poorly understood. pDCs comprise a DC population that is highly specialised to sense viral and certain microbial infections. LL37 plays a key role in converting self-DNA into a stimulatory ligand for pDCs [7], and the LL37 expression in renal biopsy tissues from PiCGN patients was strong. BDCA-2 is a pDC-specific marker [18], and we found that BDCA2 co-localised with LL37 in the glomeruli and interstitium. Furthermore, a previous report indicating that pDCs produce large amounts of IFN α in the presence of DNA and LL37 [7] suggests that IFN α may be released from pDCs in renal tissue. We also found that LL37 co-localised with IFN α in PiCGN renal biopsies, and these results indicate that pDCs are activated and participate in the inflammatory response in the kidney. As kidney injury coupled with the expression of LL37 may elicit the sustained accumulation and activation of pDCs in the kidney, LL37 antagonists may potentially be developed as therapies for PiCGN and other chronic inflammatory diseases, whereas LL37 itself may potentially serve as a vaccine adjuvant [7].

Neutrophils are considered the mainstay of the cellular innate immune response. Many data have shown that neutrophils are not only basic players and mediators of innate immunity but are also involved in the activation, regulation and effector functions of adaptive immune cells, such as dendritic cells, B cells and T cells [19,20]. In addition, there has been increased attention on extracellular neutrophil traps in recent years with regard to the pathogenesis of diverse inflammatory and autoimmune diseases [21-26]. Summers and colleagues reported that neutrophil recruitment may play an important role in experimental anti-MPO crescentic GN [27], and recent research has reported that autoantibodies against human LAMP-2 represent a new ANCA subtype that can be induced by infection with fimbriated bacteria, which occurs at a high prevalence in PiCGN cases [2,3]. We found that anti-LAMP-2-IgG triggered NET formation and that targeted auto-antigens for LAMP-2, PR3, MPO and LL37 were present within those NETs. There were also higher levels of LL37 released in AAV patients compared with HCs, as determined by NET formation *in vitro*. This result demonstrates that ANCA can activate neutrophil-released auto-antigens through NET formation. This process

results in the expression of LAMP-2, MPO, PR3 and LL37 or high-mobility group box-1 protein, which all have the characteristic dual capacity to mobilise and activate antigen-presenting cells, thereby further inducing the activation of immune cells [28]. These observations indicate that ANCA may perpetuate a vicious circle of NET production that maintains the delivery of endogenous danger signals to the immune system.

The present study provides evidence that LL37 expression is increased not only in the sera but also at the site of local renal inflammation in AAV. The serum levels of LL37 could thus reflect both local and systemic inflammation. However, further studies are needed to evaluate the clinical significance of LL37 in a larger sample as well as its value as a biomarker in AAV patients with renal involvement.

Conclusions

Together, our findings indicated that the serum levels of LL37 and IFN α levels were increased in AAV patients, particularly those with crescentic GN. These increases in the serum LL37 and IFN α levels were correlated with crescentic formation. Accordingly, the crescentic patients showed evidence of LL37 and IFN α expression in their local inflammatory renal tissue. Taken together, these data suggest that LL37 may play an important role in the renal pathology of AAV patients.

Additional files

Additional file 1: Figure S1. Showing the levels of serum LL-37 and IFN α before and after treatment. Serum levels of LL37 (A) and IFN α (B) were significantly decreased after immunosuppressive therapy than before treatment ($n = 7$, $*P < 0.05$).

Additional file 2: Figure S2. Showing expression of MPO, LL37, IFN α and BDCA2 in AAV patients with crescentic GN. (A) Representative images showing the co-localisation of MPO (green) and LL37 (red) in the glomeruli of frozen renal biopsy sections after immunofluorescence staining. (B) Co-localisation of MPO (green) and IFN α (red) in renal biopsy sections from AAV patients with crescentic GN. (C) Co-localisation of MPO (green) and BDCA2 (red) in renal biopsy sections from AAV patients without crescentic GN.

Additional file 3: Figure S3. Showing IFN α released from pDC. None IFN α were detected in the supernatants from neutrophils treated with or without anti-LAMP-2 antibodies (H4B4) for 3 hours. The mean level in the supernatants of IFN α was 7,357 pg/ml from pDCs incubated with ODN2216 groups, and was 866 pg/ml from pDCs incubated with supernatants of anti-LAMP-2 antibody-treated neutrophils. The level was under-detectable in supernatants from pDCs treated with medium.

Submit your next manuscript to BioMed Central and take full advantage of:

- Convenient online submission
- Thorough peer review
- No space constraints or color figure charges
- Immediate publication on acceptance
- Inclusion in PubMed, CAS, Scopus and Google Scholar
- Research which is freely available for redistribution

Submit your manuscript at
www.biomedcentral.com/submit
